

PATENT APPLICATION

**METHOD AND APPARATUS FOR ASSIGNING
DATA RATE IN A MULTICHANNEL COMMUNICATION SYSTEM**

5

BACKGROUND OF THE INVENTION

Field of the Invention (Technical Field):

The present invention relates to wireless communications over a variety of channels in a communication link. More particularly, the present invention relates to a method and apparatus for negotiating data rates for individual channels of a multi-channel communication system in order to remain within available transmission power corresponding to that rate.

Background Art:

Many communication systems including cellular, satellite, and point to point communication systems use a wireless link comprised of a modulated radio frequency (RF) signal to transmit data between two locations. The use of a wireless link is desirable for a variety of reasons including increased mobility and reduced infrastructure requirements when compared to wire line communications systems. One drawback of using a wireless link is the limited amount of communication capacity that results from the limited amount of available RF bandwidth. This limited communication capacity is in contrast to wire- based communication systems where additional capacity can be added by installing additional hardwire connections.

Recognizing the limited nature of RF bandwidth, various signal processing techniques have been developed for increasing the efficiency with which wireless communication systems utilize the available RF bandwidth. One widely accepted example of such a bandwidth-efficient signal processing technique is the IS-95 over-the-air interface standard and its derivatives such as IS-95-A (referred to collectively hereafter as the IS-95 modulation schemes) promulgated by the Telecommunication Industry Association (TIA) and used primarily within cellular telecommunication systems. The IS-95 modulation

scheme incorporates code division multiple access (CDMA) signal modulation techniques to create multiple communication channels simultaneously over the same RF bandwidth. In a CDMA cellular telecommunication system, multiple signals are transmitted simultaneously at the same frequency. Such a CDMA system is disclosed in U.S. Pat. No. 4,901,307 to Gilhousen et al., entitled "Spread Spectrum

5 Multiple Access Communication System Using Satellite or Terrestrial Repeaters" and in U.S. Pat. No. 5,103,459 also to Gilhousen et al., entitled "System and Method for Generating Signal Waveforms in a CDMA Cellular Telephone System", both of which are incorporated by reference. In this type of system, a particular receiver determines which signal is intended for it by a unique spreading code in the signal. Signals at that frequency, without the unique spreading code, appear as noise to that receiver and are ignored. Allowing multiple communication links over the same bandwidth increases the total number of voice calls and other communications that can be conducted in a wireless communication system by, among other things, increasing the frequency reuse in comparison to other wireless telecommunication technologies.

10 CDMA modulation employs a spread spectrum technique for the transmission of information. In a spread spectrum system, the transmitted signal is spread over a wide frequency band in a pseudorandom fashion. This frequency band is typically substantially wider than the minimum bandwidth required to transmit the signal. The spread spectrum technique is accomplished by modulating each base-band signal to be transmitted with a unique wideband spreading code. Using this technique, a signal having a bandwidth of only a few kilohertz can be spread over a bandwidth of more than a megahertz. A form of frequency diversity is obtained by spreading the transmitted signal over a wide frequency range. Since only 200-300 kHz of a signal is typically affected by a frequency selective fade, the remaining spectrum of the transmitted signal is unaffected. A receiver for the spread spectrum signal, therefore, will be affected less by the fade condition.

25

In prior art cellular telecommunication systems using CDMA, each voice circuit was assigned a unique code and transmitted on a single channel simultaneously with other voice-coded circuits using the spread spectrum technique. The receiver recovered the signal from the noise by using the same code

as the transmitter. Using CDMA, even very low power signals could be recovered by the receiver. Later CDMA systems include data transmission capability, such as electronic mail, facsimile, and Internet access, over additional channels, for use by the subscriber.

5 A highly simplified CDMA cellular telecommunication system is shown in Fig. 2. Three telephone subscriber mobile units **12a-c** are shown along with a single base station **10** within cell **100**. A cell is generally defined as a particular RF coverage area and as a mobile changes location, it will possibly move from one cell to the next. Base station **10** is a multicircuit transceiver located at the center of cell **100** whose primary purpose is to handle incoming and outgoing calls within the cell. Calls originating from a particular mobile will be relayed through base station **10**. All mobile communications occur through the base stations of each cell via RF transmission, as well as through a mobile telephone switching office (MTSO) computer that is wired to each base station. Reverse channel link **R** represents RF communication from mobile **12a** to base station **10**, while forward channel link **F** represents RF communication from base station **10** to mobile **12a**, when mobile **12a** is online.

10
15 The forward CDMA link contains one or more code channels for communication that are transmitted on a CDMA frequency assignment using a particular pilot pseudorandom noise offset. The frequency assignment is a 1.2288 MHz segment of spectrum centered on a specified channel. Current IS-95 systems always include a pilot channel, possibly one sync channel, as many as seven paging channels, and up to 63 traffic channels, providing that the total including the pilot does not exceed 64, in the forward link.

20
25 While earlier CDMA cellular telephone communications did not provide multiple channels to the subscriber in the reverse link, the reverse link of third generation CDMA cellular telephones, for example, CDMA 2000 and W-CDMA (wideband CDMA), provide different channels for access, signaling, voice, and data communications. The different channels available in the reverse link provide a more versatile and efficient communication device for the subscriber.

Attention is directed to Fig. 3 for a background discussion of reverse link CDMA channels for spreading rates 1 and 3. Spreading rate (SR) is the pseudorandom noise (PN) chip rate of a direct-sequence carrier. SR1 is 1.2288 MHz and is commonly referred to as 1X. SR3 is three times this rate, or 3.6864 MHz and is commonly referred to as 3X. Fig. 3 depicts CDMA channels and their respective "modes of operation" for two modulation schemes, the earlier IS-95 and the later CDMA 2000. Access channel **50** and reverse traffic channel operation **52** are earlier IS-95 modulation schemes. Enhanced access channel operation **58**, reverse common control channel operation **64**, and reverse traffic channel operation **70** are CDMA 2000 modulation schemes. Many current mobile units implement some of both modulation schemes. In order to transition from the earlier IS-95 to the CDMA 2000 modulation scheme, CDMA 2000 mobiles are being deployed in two design phases. The first phase CDMA 2000 mobiles operate an access channel **50** under the IS-95 modulation scheme, and reverse traffic channel operation **70** under the CDMA 2000 modulation scheme. It is intended that the second phase CDMA 2000 mobiles will replace access channel **50** with enhanced access channel operation **58** and will add reverse common control channel operation **64**. The first phase CDMA 2000 mobiles are currently in production using the SR-1 1.2288 MHz (1X) PN rate and are operable with radio configurations (RC) 3 and 4 in the reverse link. It is intended that second phase CDMA 2000 mobiles will implement a 3.6864 MHz (3X) PN rate and will operate with radio configurations 5 and 6 in the reverse link. RC is the manner in which data bits are built from the voice encoder, or vocoder, and output to the modulator. RC is defined by a "rate set" which includes transmission rate, modulation characteristics, and error correction coding schemes, as defined in the IS2000 standard specifications. For example, RC 1 has a 9600 bits per second (bps) data rate while RC 2 operates at 14400 bps. Radio configurations are typically built into an application specific integrated circuit within each mobile and relate to both the forward and reverse links.

Reverse traffic channel operation **52**, enhanced access channel operation **58**, reverse common control channel operation **64**, and reverse traffic channel operation **70** each have more than one "mode of operation" because a variety of channel modes of operation operate within their respective channel designations. Reverse traffic channel operation **52** operates in either of two modes, as a reverse

fundamental channel **54**, or up to as many as seven reverse supplemental code, or data, channels **56** in earlier IS-95 systems. Enhanced access channel operation **58** always includes a reverse pilot channel **60** along with an enhanced access channel **62**. Reverse common control channel operation **64** always includes a pilot channel **66** as well as the reverse common control channel **68**. Reverse common control channel **68** accommodates more than one user at a time and is used for the transmission of user and signaling information to the base station when reverse traffic channels are not in use. Reverse traffic channel operation **70**, operable for RC 3 to RC 6, always includes pilot channel **72** and a power control subchannel **80**. Reverse traffic channel operation **70** can also contain zero or one dedicated control channel **74**, zero or one reverse fundamental channel **76**, and zero, one, or two reverse supplemental channels **78**. Thus, reverse traffic channel operation **70** operates as one of many possible combinations of channels. First and second phase CDMA 2000 channel modes of operation are described further below.

Although the pilot channel is identified separately at **60**, **66**, and **72** in Fig. 3 for ease of reference, there is only one pilot channel. The pilot channel operates as a pilot for either enhanced access channel operation **58**, reverse common control channel operation **64**, or reverse traffic channel operation **70**, depending on which channel designation is currently being operated. The pilot channel provides timing information from the mobile for a coherent link between the mobile and base station.

Access channel **50** is used for short signaling message exchanges such as call origination, responses to pages, and registrations, and is a slotted random access channel. During access to the base station, the mobile begins with a calculated transmission output power and steps up the power using a "slotted aloha" protocol until the base station is able to demodulate the signal and acknowledges this to the mobile. At that point the output power is set and a service configuration is negotiated.

Enhanced access channel operation **58** is presently intended to be available in future releases of CDMA 2000 and will provide improved system capacity when in use.

Mobile units use the reverse common control channel **68** to sign in with the base station, gain access, and register (identify mobile location and parameters to the base station). This channel will also allow short data bursts commonly referred to as a "short messaging system" (SMS). Dedicated control channel **74** is used only for ongoing signaling information such as pilot strength, pilot set, system parameters, updates, and hand-off messages. Voice, or signaling, can be transmitted over the fundamental channels **76** by various multiplexing options. Alternatively, the fundamental channels **76** can be used exclusively for voice transmission by allocating all signaling to the dedicated control channel **74**. Up to two supplemental, or data, channels **78** are used solely for data transmission. At present, each supplemental channel **78** can be set to a data rate between 1.2 kbps and 1.037 Mbps depending upon the proximity of the base station, available power, and number of other users within the cell. Power control subchannel **80** is commonly referred to as a subchannel because it is "punctured" onto the pilot channel and controls the base station power to the mobile, in the forward link. In other words, at a particular time the pilot bits are temporarily replaced with a code instructing the base station to increase or decrease power to the mobile as needed.

Each channel mode of operation (referred to hereinafter as "channel") in the reverse link is provided with coding for spreading the signal transmitted over the channel and for distinguishing each mobile from all others in a cell. First, a short code is overlaid onto the pilot to provide pseudorandom spreading in the reverse link, and then a long code is overlaid to separate the mobile code from all others. This is accomplished through Hybrid Phase Shift Keying (HPSK), also known as Orthogonal-Complex Quadrature Phase Shift Keying (OC-QPSK), and the use of orthogonal Walsh codes. An example of this process is depicted in Fig. 4, a communications mapping diagram set out in the TIA IS-2000 specification, for a particular set of reverse link channel modes of operation: reverse pilot **60** (**66** and **72**), reverse dedicated control **74**, reverse fundamental **76**, reverse supplemental **78'**, and either of another reverse supplemental channel **78**, reverse common control channel **68**, or the enhanced access channel **62**, operable with RC 3 or 4. In Fig. 4, binary zeroes are mapped with a +1 and binary ones are mapped with a -1, unused channels and gated-off symbols are represented with zero values, and when the reverse common control or enhanced access channels are used, the reverse

pilot channel is the only other channel available. "I-channel" refers to in-phase channel and "Q-channel" refers to quadrature phase channel, the information on each being separated by 90°.

Each of the different channel modes of operation described above can come from different base

5 data rates, hence the processing gain (for a constant bandwidth) protecting the signal in the over-the-air
channel varies, and the signal-to-noise ratio required at the base station in order to decode the signal
varies. Processing gain is the ratio of the bandwidth of a spread spectrum signal to the data rate of the
information being transmitted. High processing gain is preferred for providing high system capacity and
better quality communication links. Generally, access, pilot, fundamental and dedicated control channel
10 modes of operation have a lower data rate, relatively high processing gain, and a lower signal to noise
requirement at the base station. Conversely, each data, or supplemental, channel mode of operation
generally has a higher data rate, relatively low processing gain, and a higher signal to noise requirement
at the base station. One problem that arises in CDMA communication using multiple channels is that the
base station does not know the amount of remaining power that the mobile unit can apply to a lower
15 processing gain channel when the mobile is in communication with the base station on a higher
processing gain channel. Consequently, when a lower processing gain channel does come into
operation, such as for data transmission, the call may be dropped or high error rates may occur due to
the additional power required to transmit the signal over the low processing gain channel exceeding the
power transmission capacity of the mobile unit.

20

Prior art patents discuss power control in CDMA systems but do not address the above problem
that occurs when the transmission power required increases due to the addition of one, or more,
channels. U.S. Patent No. 5,926,500 to Odenwalder, entitled "Reduced Peak-To-Average Transmit
Power High Data Rate CDMA Wireless Communication System" refers to the generation of a CDMA
25 reverse link with channels having varying processing gains and data rates. However, Odenwalder notes
that the total transmission rate can be increased either by transmission over a particular channel at
higher rates or by multiple transmission over multiple channels, or both, until the signal processing
capability of the receive system, the base station, is exceeded and the error rate becomes unacceptable,

or the maximum transmit power of the transmit system, or mobile, is reached. Odenwalder does not provide a solution for keeping the system from exceeding the acceptable error rate or maximum transmit power of the mobile which results in dropped calls. U.S. Patent No. 5,812,938 to Gilhousen et al. entitled "Reverse Link, Closed Loop Power Control In a Code Division Multiple Access System" describes a
5 method for instructing the mobile to increase or decrease its power depending upon the required E_b/No for a particular data rate. (Signal to noise ratio is routinely defined as: E_b/No , where " E_b " represents the energy per digital bit period and " No " represents noise.) Like Odenwalder, this patent also does not address the issue of dropped calls when the addition of a reverse channel causes the mobile to exceed its maximum transmitter power output, but rather only recognizes the need for increasing transmitter power to meet the required E_b/No of the base station receiver.
10

When the mobile is gaining access to the telecommunication system, it negotiates the channel configuration based solely on its ability to generate the required data rate. The mobile does not communicate its transmission power capability. Power capability is assumed because the mobile is indeed in communication, but it is in communication at this point only because it is using a higher processing gain channel (at or below 14.4 kbps). It will increase the slotted aloha probe only to determine where the higher processing gain channel is successfully demodulated by the base station.
15 Consequently, when a higher data rate, lower processing gain channel comes into operation, there may not be enough power available from the mobile on the reverse link to sustain the communication
20 connection.

This lack of power availability problem also arises when the mobile changes location in relation to the base station or the cell environment changes. For example, after a data rate has been negotiated, the mobile may discontinue transmission of the data channel periodically because there is no data to be
25 transmitted. During this quiescent period, communication between the base station and the mobile is maintained using only the higher processing pilot gain channel. If the mobile changes location during this period, the amount of required transmit power for the data channel may change. If the mobile moves away from the base station, there will be less power available to transmit on the reverse data channel

when it is required; if the mobile moves closer to the base station, more power may be available. Other objects, such as large vehicles, in the path of the RF signal, may block signal transmission to and from the mobile, thereby changing the power requirement. When the data channel comes back into operation at the former data rate, the power it demands may cause the signaling channel power to drop below the receiver requirements of the base station and the call may be dropped. Table 1 below provides an extreme example of the relative power required for three channels, pilot, dedicated control, and supplemental, in a signaling-only versus a data transmission communication at 153.6 kbps, for an IS-98D standard, Class III mobile that is transmitting at a constant power output of 23 dBm, operating in band class 0.

Channel Power Required (dBm)

Signaling (Control Hold)	Active Data (153.6 kbps)
Pilot = 17.7	Pilot = 11.8
Dedicated Control = 21.5 (9600 bps)	Dedicated Control = 11.1 (9600 bps)
	Supplemental Data = 22.4

Table 1

The example in Table 1 demonstrates that during signaling the pilot must transmit at 17.7 dBm to maintain a connection to the base station, and the dedicated control channel must transmit at 21.5 dBm. However, in order for the subscriber to begin transmitting data at the 153.6 kbps rate, the transmission power available for the dedicated control and pilot channels would have to drop substantially, which would result in a lost connection to the base station and a dropped call.

Because the newer CDMA telecommunication systems provide pilot, dedicated control, supplemental control, data, and voice in the reverse link, it is difficult to obtain enough power from currently available RF amplifiers used in mobile transmitters. One way to retain current RF power amplifier designs and remain within the usable linear portion of these amplifiers, is to negotiate the

communication data rate in the reverse link based upon the channel or channels being used, so that the addition of a data channel, or channels, to other active channels, does not require transmission power that exceeds available output power. Current telecommunication systems have no method by which the base station is provided with prior knowledge of the mobile transmitter power status during

5 communication over higher processing gain channels. Accordingly, there is a great need for a method that allows the mobile and base station to negotiate a data rate for low processing gain channels while in communication over higher processing gain channels. It would be beneficial if the system could remain within the maximum transmit output power capacity of the mobile when the low processing gain channel comes online and thus avoid dropped calls. This method should additionally allow the mobile to adjust

10 the data rate to remain within available transmitter power when the mobile changes location within a cell, when the mobile moves to a different cell, or when the cell environment changes.

SUMMARY OF THE INVENTION (DISCLOSURE OF THE INVENTION)

A primary object of the present invention is to negotiate data rates for lower processing gain channels of a multi-channel communication system such that transmission is maintained within available transmission power. Another object of the present invention is to reduce lost connections between the transmitter and receiver, make more efficient use of available transmission spectrum, and increase the transmission data rate to the maximum possible without exceeding available transmission power.

20 The present invention provides a method of negotiating the data rate between a transmitter and a receiver in a communication system wherein transmission occurs over a plurality of channels in a particular link. The method results in assigning a data rate such that the power required to transmit at that data rate does not exceed the output power capability of the transmitter.

25 The present invention provides enhanced CDMA wireless communication system performance by maximizing data rates according to the available mobile output power for systems having multiple channels each with varying processing gains. A primary advantage of the present invention is the ability to provide increased data rates to subscribers of wireless communication services due to more efficient

use of available power and the fixed RF frequency bandwidth. Further, because data rates are negotiated so that transmission occurs within available power limits, fewer calls are dropped. Another advantage of the present invention is increased capacity for wireless communication system carriers. Capacity is increased because there are fewer dropped calls and therefore fewer access attempts.

5

Other objects, advantages and novel features, and further scope of applicability of the present invention will be set forth in part in the detailed description to follow, taken in conjunction with the accompanying drawings, and in part will become apparent to those skilled in the art upon examination of the following, or may be learned by practice of the invention. The objects and advantages of the invention may be realized and attained by means of the instrumentalities and combinations particularly pointed out in the appended claims.

10

BRIEF DESCRIPTION OF THE DRAWINGS

The accompanying drawings, which are incorporated into and form a part of the specification, illustrate several embodiments of the present invention and, together with the description, serve to explain the principles of the invention. The drawings are only for the purpose of illustrating a preferred embodiment of the invention and are not to be construed as limiting the invention. In the drawings:

15

Fig. 1 is a flow chart of the preferred method of the present invention;

20

Fig. 2 is a diagram demonstrating the forward and reverse links of a CDMA cellular telecommunications system;

25

Fig. 3 is a diagram of typical reverse link CDMA cellular telecommunications system channels;

Fig. 4 is a communications mapping diagram for the reverse link CDMA channels of Fig. 3;

Fig. 5 is a block diagram of prior art CDMA cellular telecommunication mobile unit structure within which the method of the present invention is implemented; and

Fig. 6 is a diagram depicting mobile output power at two different locations with respect to the
5 base station within a cell.

DESCRIPTION OF THE PREFERRED EMBODIMENTS

(BEST MODES FOR CARRYING OUT THE INVENTION)

The present invention addresses the problem of exceeding the maximum mobile transmitter
10 output power and potentially losing connection to the base station in CDMA systems having multiple channels in the reverse link when low processing gain channels are brought online in addition to other channels. The invention is a method and apparatus for negotiating the maximum possible data transmission rate for a low processing gain channel. The mobile proposes a data rate to the base station receiver based upon available mobile transmitter output power.

15 Current mobile units complying with IS-95 standards can be calibrated to limit the maximum allowable mobile transmitter output power based solely upon the usable linear portion of the mobile RF power amplifier. Fig. 5 is a block diagram of the CDMA mobile structure within which a data rate control method may be implemented. The maximum output power limit is presented to processor 22
20 within the mobile as a digital value in memory 24 which is then compared to an input from mobile peak power detector 26 that has been fed through analog to digital converter (ADC) 28 and further converted to a linearized digital value from a look-up table. If the value for peak power detector 26 is higher than the calibrated limit, processor 22 reduces the output power from RF amplifier 20 to antenna 34 through an existing power control function represented by 30 in Fig. 5. Modulator 32 receives the signal to be
25 transmitted and modulates it for RF transmission to the base station.

An object of the present invention is to control the data rate such that available power is not exceeded. When transmitting on the high processing gain, and pilot, channels in the reverse link, the

mobile is aware of its output power due to "open loop" and "closed loop" power control implemented by processor 22 and power control 30. Generally, in CDMA telecommunications, the mobile initially estimates and transmits at an output power based upon the received signal strength from the base station, commonly referred to as "open loop" power control. Then, power control (PC) bits from the base

5 station override open loop power control directing the mobile to transmit at a particular output power based upon the received signal power at the base station, which is referred to as "closed loop" power control. This results in a calibrated automatic gain control value (AGC) at which the transmitter output power is to operate. The mobile is also capable of determining, as discussed below, the amount of additional power it requires to transmit a new negotiated data channel rate that it is preparing to transmit.

10 Current mobile output power is added to the power required to transmit at the negotiated data rate over the data channel before the data channel comes online. If this projected total exceeds the maximum capability of the mobile, a lower data rate is selected; if the projected total is substantially below the maximum capability of the mobile, a higher data rate is selected. This process is repeated until the maximum data rate is selected that will allow transmission within an acceptable power output range. The mobile then proposes this data rate to the base station, and the base station either accepts or rejects the proposed rate. This process takes place within a stated time frame that may be established for a specific implementation, i.e., balancing the objective of highest possible data rate versus user access time to the channel.

20 In a first preferred embodiment of the invention, a table of relative powers at particular data rates is compiled. The table of relative powers shows the power level of each high processing gain channel relative to the low processing gain channel, or supplemental channel, at different data rates. The table is loaded into a look-up table (LUT) in memory in the mobile unit. Table 2 provides an example. These particular values are derived from known reverse link nominal attribute gains for data rates between

25 1.2 kbps and 1.0368 Mbps as published in the TIA/EIA/IS-2000.2-A-1 standard. These values are adjusted by the known mean code channel output power equation taken from the TIA/EIA/IS-2000.2-A-1 standard:

mean code channel output power (dBm) = (1)

mean pilot channel output power (dBm)

+ 0.125 x (Nominal Attribute Gain [Rate, Frame Duration, Coding]

+ Attribute Adjustment Gain [Rate, Frame Duration, Coding]

+ Reverse Channel Adjustment Gain [Channel]

- Multiple Channel Adjustment Gain [Channel]

- Variable Supplemental Adjustment Gain [Channel]

+ RLGAIN TRAFFIC PILOT_s

+ RLGAIN SCH PILOT [Channel]_s)

+ IFHHO SRCH CORR,

where "code channel" and ["Channel"] identify either the reverse fundamental channel, reverse dedicated control channel, or any of the reverse supplemental channels. Table 2 assumes a mobile transmitter capable of a maximum output power in the range of 23 to 30 dBm (200 to 1,000 mW), for an IS-98D standard, class III mobile operating in band class 0. The example depicted in Table 2 shows power levels for the pilot, dedicated control and fundamental channels relative to the supplemental channel (0 dB), with the output for the pilot channel remaining constant at 59.3 mW across each column for different supplemental channel transmission data rates. Table 2 assumes a constant mobile signal strength requirement based on signal environment in relation to a base station.

LUT Relative Powers (dB)					
Data Rate (bps)	9600	19200	38400	76800	153600
Pilot	-3.75	-6.25	-7.5	-9.0	-10.5
Dedicated Control (9600 bps)	0	-2.65	-5.125	-7.875	-11.25
Fundamental	0	-2.65	-5.125	-7.875	-11.25
Supplemental	0	0	0	0	0

Table 2

The relative powers in Table 2 can be described with reference to the absolute powers in

Table 1. Referring to Table 1, in a signaling-only communication from a mobile at a transmitter output power of 23 dBm (200 mW), the pilot channel requires 17.7 dBm (59.3 mW) and the dedicated control channel requires 21.5 dBm (140.7 mW). In other words, in order to maintain contact with the base station at that mobile location within the cell, the pilot channel must be maintained at 17.7 dBm, and the dedicated control channel must be at least 3.75 dB above the pilot channel power of 17.7 dBm, or 21.5 dBm. This relative power is shown in the first column of Table 2. According to the first column of Table 2, if a supplemental channel is brought online at a data rate of 9600 bps, in addition to the already-active, high processing gain, pilot and dedicated control channels, it would also require 21.5 dBm (140.7 mW), because it is also 3.75 dB above the pilot channel. Therefore, the absolute output power required by the active channels prior to bringing the supplemental channel online is 200 mW, or 23 dBm. The projected absolute output power required once the supplemental channel came online would be 59.3 mW (pilot) + 140.7 mW (dedicated control) + 140.7 mW (supplemental) = 340.7 mW, or 25.3 dBm, which is safely within the maximum output power capability (30dBm) of the mobile transmitter. The fundamental channel would also require 140.7 mW if it were brought online.

In the second column of Table 2, for a higher data rate, the pilot channel still requires 17.7 dBm (59.3 mW) of power to maintain the connection with the base station. According to the second column of

Table 2, the dedicated control channel power required is (-2.65 - (-6.25)) or 3.6 dB above the pilot channel power (134.9 mW), and the supplemental channel would require 6.25 dB more power than that of the pilot channel if it were brought online at 19200 bps (248.3 mW). The relative pilot power increases slightly in successive columns in Table 2 to maintain coherency in the communication link; as there is
5 less processing gain on the supplemental channel, the timing must be highly accurate. Therefore, the absolute output power required for the two active channels prior to bringing the supplemental channel online is 194.2 mW, or 22.8 dBm, and the projected absolute output power required if the supplemental channel were added at 19200 bps would be 442.5 mW, or 26.4 dBm. Similar calculations can be made for the remaining three columns of Table 2.

10 While Table 2 shows only a single supplemental, or data, channel, it is to be understood that the invention has application when any number of channels are brought online. The present invention has application to any combination of the reverse link channels shown in Fig. 3 as well as to others not shown or described, as will be understood by those skilled in the art. The relative powers of the LUT can 15 optionally be updated by the mobile processor based upon signaling from the base station for a change in relationship between the base powers. (See Eqn. (1)). Additionally, as one skilled in the art would understand, the relative powers in Table 2 can be in reference to the power of any convenient channel, in lieu of that of the supplemental channel.

20 When a data channel is requested, the mobile determines from the LUT the maximum data rate that the mobile is capable of sending without exceeding the RF amplifier power output capability. The maximum data rate is determined based upon the real-time operating conditions of the mobile. When the mobile negotiates the addition of a supplemental, or data, channel, the processor determines the relative power required by the currently-negotiated, or default, data rate for the data channel from the 25 LUT, as described in the above example of Table 2. The processor then adds this amount of power to the power required by the other active reverse link channels currently being transmitted to determine the projected output power required of the mobile due to the addition of a data channel at that data rate. This projected power is compared to the maximum power capability of the mobile, that is stored as a

digital value in memory. If the projected power is less than the lower level of a pre-selected tolerance (to be described further below) of the maximum output power, then the processor selects a higher data rate. The processor again determines the projected output power due to the addition of a data channel at the higher data rate, to the other active channels in use, and compares this to the maximum output power
5 capability. If the negotiated data rate results in a projected output power that is above the maximum power capability, a lower data rate is selected and the projected power determination and comparison steps are repeated. This process of evaluating higher and lower data rates for projected output power is repeated until the projected output power is within a pre-selected tolerance range of the mobile maximum power.

10 Referring to Fig. 1, a flow chart demonstrates the method by which the mobile determines the maximum data rate for a data channel that is to be added to transmission, as well as to periodically review the currently-negotiated, or default, data rate. The method is preferably implemented in the mobile processor. First, the mobile unit processor, through a suitable algorithm, estimates current RF amplifier output power by averaging a series of measured power output values obtained from processor 22. The transmitter AGC value can be used as this estimate. The AGC value is input to processor 22 through open and closed loop power control over a given period of time. (See Fig. 5.) In the second step, the processor executes a routine to determine the relative power required by the data channel at a first data rate, which is the currently-negotiated or default data rate, with reference to other
15 active high processing gain channels by accessing a LUT in memory, similar to that of Table 2. It is to be understood, however, that a suitable equation can serve the same purpose as a LUT in determining
20 the relative power required for the data rate.

25 From the relative gain in the LUT, the processor determines the power required by the data channel and adds the required power to current RF amplifier output power to arrive at a projected output power. In the third step, the processor executes a comparison routine that compares the projected absolute (dBm) output power to the maximum absolute (dBm) output power capability of the mobile RF amplifier. The comparison is preferably made between digital values; the projected absolute power is

converted from a dBm value to a digital value that is then compared to the maximum output power capability stored as a digital value in memory. If the projected output power falls within a pre-selected tolerance range of the maximum power capability, then transmission occurs at that rate.

5 If the projected output power is above the maximum power capability, then the mobile selects a lower data rate and repeats the process of determining the power required for the data channel at that data rate, as described above. The data rate is repeatedly lowered, if necessary, until a data rate is located that results in a projected output power within a pre-selected tolerance of the maximum output power capability. It will be appreciated that different algorithms may be chosen by which the data rate is selected resulting in a projected output power within the pre-selected tolerance of the maximum. For example, the data rate step size and therefore the projected output power step size may vary. Additionally, the sequence of changes in data rate and therefore in the projected output power may be either increases or decreases in any order.

10 If the lowest data rate has been reviewed and the power required is not available, the mobile will not open a data channel. The tolerance can be seen in Fig. 6, a diagram depicting mobile transmitter output power at 40. Fig. 6 shows the maximum output power capability of the mobile transmitter, along with a tolerance range within which the projected output power is acceptable. Projected output power is accepted within the tolerance range to prevent excessive renegotiation of the data rate.

15 If the negotiated, or default, data rate results in a projected output power that is below the lower tolerance level, as can be seen in Fig. 6, then a higher data rate is selected by the processor. The processor then determines the power required for the data channel at that data rate, determines the projected output power, and compares the projected output power to the maximum output power as described above. Higher data rates are repeatedly evaluated, as necessary, until the projected output power falls within the pre-selected tolerance of the maximum output power capability. Once a data rate is found which results in a projected output power within the pre-selected tolerance range, that rate is

proposed to the base station for transmission, if different from the default or currently-negotiated data rate.

Another step may be performed to monitor the number of negotiations that have occurred

- 5 between the mobile and base station within a stated time period, such as during a call, to prevent the mobile from increasing the data rate too frequently. The processor monitors the number of negotiations that have occurred in the stated time period and compares that number to a value stored in memory. If the number of negotiations is above the stored value, then it is placed in a periodic review mode and the data rate is held at the currently-negotiated, or default, rate rather than being renegotiated. While in the periodic review mode, the processor reviews the relative power required for the currently-negotiated data rate and the projected output power periodically, to determine whether the data rate should be increased or decreased due to changes in available mobile transmitter output power, as described below.

Once a data rate is found that results in a projected output power within the pre-selected

- 15 tolerance, the mobile sends an origination, page response, service request, or supplemental channel request message to the base station proposing that data rate. Once the base station accepts the proposed data rate, it sends a service connect message to the mobile. The mobile then responds with a service connect completion message to the base station and implements the configuration. Optionally, the negotiated data rate is then stored as the currently negotiated rate in memory and replaces the
20 default data rate so that the next time the data rate power is determined the process begins with the most recent rate for a period of time. Upon power down, the data rate is then restored to the original default data rate value.

The periodic review mode allows the mobile to reassess its power availability and increase or

- 25 decrease the data rate accordingly. If, for example, the mobile moves closer to the base station it may have increased available power due to the decreased transmission distance. Referring to Fig. 6, mobile **12** is shown within a cell at two different times, and two different corresponding locations, l_1 and l_2 , in relation to base station **10**. When mobile **12** is further away from base station **10** at location l_1 , it is

transmitting within the pre-selected tolerance range as shown in the power diagram 40, and operates a data channel at a currently-negotiated data rate of x in the reverse link. When mobile 12 moves closer to base station 10 to location l_2 , the power control function in the forward link causes mobile 12 to transmit at a lower output power as shown in the power diagram 40. Because the relative power required for the 5 currently-negotiated data rate is periodically reviewed, mobile 12 may be able to select a higher data rate than x , due to the available output power. Conversely, if mobile 12 moves to a location farther from base station 10, the data rate may be decreased to remain within the maximum output power capability of the mobile. This method is also applicable during hand-off, when the mobile moves to a different cell resulting in a change in base station. A change in base station can result in increased or decreased 10 available mobile transmitter output power due to increased or decreased receive power at the new base station, respectively. Optionally, a review is triggered upon hand-off so that the data rate can be increased or decreased if possible to use newly available output power or necessary to avoid a dropped call, respectively.

15 While in the periodic review mode, the data rate can be renegotiated even if the mobile is presently transmitting data over a low processing gain channel. If the mobile is currently transmitting data, the processor first estimates the current output power, which in this instance includes the power required to transmit data. Then this power is compared to the maximum output power capability of the transmitter. If the current output power is within the pre-selected tolerance range, then the data rate 20 remains unchanged by the processor. If the current output power is outside of the tolerance range, then a higher or lower data rate is evaluated by referencing the LUT. First, because the current output power included power required for data transmission over a low processing gain channel, or channels, the amount of power required to operate only the high processing gain channels is determined by referencing the LUT for the relative power required of each channel in operation, and the power required 25 by the low processing gain channel, or channels, that are currently in operation is ignored. Once the power required to operate only the high processing gain channels is determined, then the relative output power required for the data rate being evaluated can be added to that power to determine the projected

output power for that data rate. Higher and lower data rates are evaluated until a data rate is located with a projected output power within the pre-selected tolerance of the maximum output power.

Once an appropriate data rate has been selected, that rate is proposed to the base station. As before, the number of renegotiations is limited to prevent excessive messaging to the base station. In the alternative, rather than determining relative and projected powers for particular data rates, the processor can simply increase or decrease the data rate by one or more levels, based upon the comparison between the current output power and the maximum output power, and propose that data rate to the base station. This may result in increased messaging with the base station, but eliminates the added step of separating the power associated with the high processing gain channels from the power associated with the low processing gain channel, or channels, over which data is currently being transmitted.

In a second embodiment of the invention, output power for the high processing gain channels is falsely limited and renegotiation is accomplished at the base station due to the received frame error rate of the data transmitted to the base station. As in the first embodiment, the mobile is programmed with the relative power requirements for each channel. Power for the low processing gain channel is then reserved by limiting the total output power available to the higher processing gain channels when they are the only channels active, so that there is enough power remaining for the low processing gain channel or channels when brought online. This effectively limits the range of the mobile to its intended data capabilities, for example, to a data rate of 38.4 kbps. For example, if the processor limits the output power allocated to the pilot, dedicated control and fundamental channels to 81.4 mW, 140.7 mW and 140.7 mW respectively when the three are in operation, then 458 mW are automatically reserved for the supplemental channel to come online at 38.4 kbps. (See Table 2.) If the base station attempts to increase the mobile output power through reverse link power control, the frame error rate at the base station will increase. The base station then independently determines whether a renegotiation for a different data rate, or handoff is required if the frame error rate is excessive, without additional messaging.

A novel method for negotiating the data rate for a particular communication channel in a multi-channel system has been described with respect to the reverse channel link of a cellular telecommunications system. Although particularly suited for such use, the present invention is also applicable to multiple channel transmission in other types of systems. Satellite-based wireless communication systems, optical communication systems, wired digital communication systems, and systems transmitting radio frequency signals via co-axial or other broadband cables benefit through incorporation of the invention. The present invention has application in any multi-channel communication system having limited transmission power output.

10 Although the invention has been described in detail with particular reference to these preferred embodiments, other embodiments can achieve the same results. Variations and modifications of the present invention will be obvious to those skilled in the art and it is intended to cover in the appended claims all such modifications and equivalents. The entire disclosures of all references, applications, 15 patents, and publications cited above are hereby incorporated by reference.
